Machining Cell Analysis

A machining cell is normally a group of machines arranged so that they are physically close to one another. The parts output from the first machine in the cell feeds the parts input to the second machine in the cell, whose parts output feeds the third machine, and so on throughout the cell. Two types of machining cells are commonly used; what can be called non-dedicated and dedicated machining cells. Non dedicated machining cells are used to process families of similar parts and have the advantage that the machines within the cell are set up once to process all of the similar parts made in the cell. Non-dedicated machining cells are commonly used when groups of similar parts are made in lower production volumes. On the other hand, dedicated machining cells are used to process a single type of part. Dedicated machining cells have the advantage of decreased part handling and increased production rate and are normally used for parts made in higher production volumes.

The following tutorial demonstrates how you can compare the cost of a part machined in a dedicated machining cell with one part machined using individual machine tool setups. Normally, to make this comparison, you would first perform a normal machining analysis for your part. However, for this tutorial, we will use one of the analyses provided in the sample files.

1. Start DFM Concurrent Costing and select Open from the File menu. In the Open data file dialog choose the machined or cast part.dfmx file from the \data\samples folder and click the Open button.

2. On the Stock separate setups analysis tab, change the life volume to 100,000 and click Calculate.

3. Right click the Stock separate setups analysis tab and select Copy, then right-click again and select Paste. Rename the new tab Cell.

4. Click the Milltronics GL6 turning center entry on the Process chart and note in the response panel on the right that the cycle time per part is 907.31s. Click the Haas HMC HS-1 entry on the Process chart and note that the cycle time per part is 293.88s. Click the Kitamura CNC drilling center and note that the cycle time per part is 118.07s. A machining cell with these machines and cycle times per part would produce a completed part every 907.31s; the cycle time for the turning center which is the bottleneck machine. This indicates a rather poorly designed machining cell because the milling machine and drilling center would be idle for much of the time. Our objective in the design of this machining cell is to balance the cycle times per part for the individual machines in the cell in order to minimize machine idle time. In this case we will consider arranging two turning centers in the machining cell to share the work of one and reduce the cycle time of the bottleneck machine.

5. Right-click the Milltronics GL6 turning center entry in the Cell analysis and select Insert Machine Tool Setup from the pop-up menu.

6. In the Insert machine dialog that appears, expand the Lathes category and double-click the Milltronics GL6 turning center to add that machine to the analysis. Close the Insert machine dialog.

7. Drag and drop the following operations from the first turning center to the new turning center:
   - The second rough cylindrical turn operation
     Drill single hole
     Finish cylindrical bore
   - The last two finish face operations
8. Click the *Setup/load/unload* operation beneath the first Milltronics GL6 turning center setup and change the number of reversals to 0.

9. Click the *Setup/load/unload* operation beneath the second Milltronics GL6 setup and select a 3-jaw chuck workholding device. Click **Calculate**.

10. Now note that the cycle times for the four setups are 436.99, 478.99, 293.88 and 118.07s respectively. Although this machining cell is still far from balanced, it is significantly improved from the cell that contained only one turning center.

11. Click the *Generic stainless steel machined/cut from stock* entry on the process chart and click the **Select process and material** button.

12. In the Process and Material Selection dialog, expand the *Machining or cut from stock* process category. Select the *Machining cell* process. For the material, select *Generic stainless steel* from the *Stainless steel* category and click **OK**.

**Study the machining cell results**

1. Click the *Machining cell results* entry on the Process chart and observe the results displayed in the right hand column.
2. Note that the program has selected the longest of the four machine cycle times for the Cell cycle time. Also note that the Cell rate is the sum of the machine rates for all machines within the cell plus the rate for the number of cell operators required. The Automatic transfer device rate field allows you to simulate a cell where transfer (load/unload/reversals) between machine tools is carried out automatically – with a robot for example.

3. Click Cost Totals Bar Chart from the Results menu. In the Select analyses group box, select the Stock separate setups and Cell analyses.

![Graph Window](image)

4. The total cost per part for the part produced in a cell is $53.22 compared with $54.58 for the part produced on separate setups. However, the cost of material is $35.77 and therefore the non-material cost savings from machining in the cell is just under 9% ($17.45 compared with $18.81).
